1 Introduction

2 Osteoporosis is a common condition characterised by decreased bone density and associated with increased risk for
3 fragility fractures, which affects almost 30% of women aged ≥ 50 years [1]. It was estimated that in 2005, over 2
4 million incident fractures occurred in the United States, with hip fractures accounting for more than 70% of the
5 costs. By 2025, annual fractures and costs could rise by almost 50% [2].

6 Fracture prevention is thus the key focus of anti-osteoporotic therapy, reducing the disease burden both for the
7 affected patient but also on the population level. Several pharmacological agents are available for primary and
8 secondary prevention. The choice of anti-osteoporotic agent largely depends on history of fragility fracture and
9 anticipated fracture risk. Oral bisphosphonates (BP) are first line treatments for postmenopausal patients with
10 increased fracture risk in clinical guidelines (#AACE/ACE 2020) as for their favourable cost-effectiveness and
11 safety profile. Teriparatide, a parathyroid hormone analogue administered as a daily injection, was approved by the
12 FDA in 2002 as the first anabolic agent for treatment of severe postmenopausal osteoporosis. While clinical trials
13 among patients with previous vertebral fractures showed a substantial risk reduction for new vertebral fracture
14 comparing teriparatide to placebo [3] and risedronate [4], its efficacy on low-incident major osteoporotic fractures,
15 especially hip fractures, is less well established: Previous randomised trials assessing hip fracture comprised only
16 few events, thus not providing sufficient power to show differences between treatment groups when studying
17 comparative effectiveness. A recent meta-analysis by Diez-Perez and colleagues assessed the effect of teriparatide
18 on hip fracture, indicating a significant 80% risk reduction compared to placebo and a non-significant 46% risk
19 reduction when compared to active controls [5].

20 With teriparatide-containing biosimilars being launched in recent years, treatment costs dropped significantly.
21 Subsequently, the discussion of cost-effectiveness in patients with less severe forms of osteoporosis is restarting.
22 Therefore, evaluation of the effectiveness in hip fracture prevention is required. In particular, observational studies
23 assessing comparative effectiveness in a real-world setting are required, as effectiveness may differ from clinical trial
24 as for differences in patient's persistence and adherence to their anti-osteoporotic treatment. While hip fracture is a
25 comparatively rare outcome, it is unambiguously defined and reliably recorded in routinely collected data, allowing
26 for a direct comparison to results from clinical trial meta-analyses. While results from non-controlled, observational
27 studies suggest that teriparatide may reduce the risk of hip fractures [6,7], this is the first observational study
28 assessing teriparatide in hip fracture risk reduction compared to oral bisphosphonate users in postmenopausal
29 women using multiple large real-world databases.

30 **2 Methods**

31 **2.1 Study design**

32 We performed a retrospective new user cohort study to estimate the effectiveness of teriparatide compared to
33 oral bisphosphonates in patients with osteoporosis[8]. We included female participants above the age of 50 with
34 established osteoporosis (any condition occurrence of hip, wrist, spine or shoulder/humerus fracture in their history,
35 prior to treatment initiation) and at least 365 days of continuous observation period before the index event. Patients
36 were considered to be new-users if they received no anti-osteoporosis drugs (raloxifene, bazedoxifene, denosumab,
37 abaloparatide, romosozumab) 365 days prior to treatment initiation with teriparatide or an oral bisphosphonate.

38 Our primary efficacy outcome was hip fracture. Vertebral fracture and a composite major osteoporotic fracture,
39 defined as hip, vertebral or wrist/forearm/proximal humerus fracture, were our secondary efficacy outcomes. We
40 excluded patients that had experienced the outcome under study any time prior to treatment initiation. Patient
41 time-at-risk started 1 day after treatment initiation and finished 730 days after treatment initiation.

42 **2.2 Data sources**

43 We ran our analyses on three US observational databases mapped to OMOP-CDM version. More specifically:

- 44 ▪ **IMB MarketScan Commercial Database (CCAE)** includes health insurance claims across the continuum
45 of care (e.g. inpatient, outpatient, outpatient pharmacy, carve-out behavioral healthcare) as well as enrollment
46 data from large employers and health plans across the United States who provide private healthcare coverage
47 for more than 155 million employees, their spouses, and dependents. This administrative claims database
48 includes a variety of fee- for-service, preferred provider organizations, and capitated health plans.
- 49 ▪ **Optum De-Identified Clininformatics® Data Mart Database – Date of Death (Optum-DOD)**: is derived
50 from a database of administrative health claims for members of large commercial and Medicare Advantage
51 health plans. The database includes approximately 17-19 million annual covered lives, for a total of over
52 65 million unique lives over a 12 year period (1/2007 through 12/2019). The population is geographically
53 diverse, spanning all 50 states.
- 54 ▪ **Optum de-identified Electronic Health Record Dataset (Optum-EHR)** is derived from dozens of
55 healthcare provider organizations in the United States, that include more than 700 Hospitals and 7000
56 Clinics; treating more than 102 million patients receiving care in the United States.

57 2.3 Statistical analyses

58 We carried out two sets of analyses. First, we derived overall treatment effect estimates of teriparatide compared to
59 oral bisphosphonates regarding the three outcomes of interest. To account for potential measured confounding we
60 developed separate large-scale propensity score models within each database based on LASSO logistic regression
61 using the same predefined set of measured covariates [8]. We estimated treatment effects using Cox proportional
62 hazards models with treatment as the sole covariate fitted in the 1:4 propensity score-matched subset of the
63 considered patient population. Hazard ratios (HR) derived in different databases were summarized using random
64 effects meta-analysis.

65 For the second set of analyses, we used the standardized framework for risk-based assessment of treatment effect
66 heterogeneity, that follows the directives of the PATH statement [9,10]. Following data extraction, the framework
67 was applied in two steps. First, we derived individualized risk predictions for the three efficacy outcomes. We built
68 the prediction models using LASSO logistic regression on the propensity score matched (1:4) subpopulation of the
69 pooled treatment arms, aiming to remove any effect of measured confounding that may cause differential fit of our
70 models across treatment arms. We considered the same large set of candidate covariates as for the development
71 of the propensity score models.

72 For each outcome we used the derived prediction models to divide the population in 4 equally-sized subgroups,
73 based on the quarters of the predicted risk distribution. Within each of these risk-based subgroups we developed a
74 new propensity score model. Our analyses were performed on the propensity score matched (1:4) subset of the risk
75 subgroup subset. We derived relative effect estimates using Cox proportional hazards models only with treatment
76 as a predictor. Absolute effect estimates were calculated based on the difference of the Kaplan-Meier estimates,
77 on day 730 after treatment initiation.

78 For each outcome we used the derived prediction models to divide the population in 4 equally-sized subgroups,
79 based on the quarters of the predicted risk distribution. Within each of these risk-based subgroups we developed a
80 new propensity score model. Our analyses were performed on the propensity score matched (1:4) subset of the risk
81 subgroup subset. We derived relative effect estimates using Cox proportional hazards models only with treatment
82 as a predictor. Absolute effect estimates were calculated based on the difference of the Kaplan-Meier estimates,
83 on day 730 after treatment initiation.

84 Residual study bias from unmeasured confounding can still be present in observational studies, which often may
85 not be visible when evaluating propensity score adjustment. To account for that, we considered a set of 126
86 negative control outcome experiments, where a null effect was assumed to be true. We used the estimated relative
87 effects for these outcomes to derive an empirical approximation to the true null distribution, which was then used

⁸⁸ to calibrate the hazard ratios and their 95% confidence intervals for the 3 outcomes of interest [11,12].

89 **3 Results**
